BISTATIC LASER RADAR APPARATUS

This invention relates to laser radar (lidar) apparatus and more particularly to bistatic coherent laser radar (CLR) apparatus.

5

Lidar devices are well known, and have been used for a variety of purposes for many years. The basic principle of lidar is to direct a laser beam to a remote target and to detect the returned signal. Modulation of the amplitude of the transmitted laser beam allows simple range information to be determined. Furthermore, the use of coherent laser radar (CLR) permits the measurement of any Doppler shift in the frequency of the returned signal thereby enabling information on the relative speed of the target to be measured. Differential absorption lidar (DIAL) devices are also known in which laser light of two wavelengths is transmitted to a target and the difference in absorption of the first and second wavelengths is used to provide a measure of the molecular concentration of a particular gas species.

15

CLR devices have been widely used for velocimetry measurements of both soft and hard targets. For example, CLR vibrometry has been used to measure the vibration characteristics of hard targets such as engine casings. CLR has also been used for Doppler wind-speed measurements. In the case of wind speed measurements, the returned signal arises from back-scatter of the transmitted laser beam off small particles (aerosols) such as dust and water droplets. Doppler wind speed measurements have been shown to be useful in a wide range of applications including meteorology, aircraft true airspeed, and detection of aircraft wake vortices.

25

Measurement of the Doppler frequency shift to a high accuracy is typically achieved in CLR devices by beating (heterodyning) the return signal with a stable local-oscillator beam, usually derived from the same laser as the transmit beam. An example of an optical fibre based CLR system is described in Karlsson et al, Applied Optics, Vol. 39, No.21, 20 July 2000.

30

It is possible to broadly categorise lidar systems as being monostatic or bistatic. Monostatic lidar systems are so called because they have common transmit and receive optics. Bistatic lidar systems derive their name from having separate transmit and receive optics.

5

In a monostatic system, spatial resolution is achieved by focusing the combined transmit/receive beams to the target. In practice, it has been found that diffraction restricts monostatic CLR systems to operation within ranges of a few hundred metres. More-over, slow drop-off in sensitivity away from the focus can result in a  
10 poorly defined probe volume. In the case of wind velocity measurements, clouds, smoke or other objects away from the probe volume may result in the generation of spurious reflections. In the case of monostatic CLR systems, it has also been found that internal parasitic reflections from the common transmit/receive optics significantly degrade system performance making such systems unsuitable for some  
15 long-range applications (e.g. vibrometry) in which a low intensity return signal is detected.

In contrast to monostatic systems, bistatic CLR systems have been found to be well suited to longer range vibrometry and some wind-speed measurements. The non-  
20 parallel transmit and receive beams can be arranged to intersect at a certain point thereby accurately defining a probe volume (e.g. an area in space or the surface of a hard target). Although confinement of the probe volume may lead to a reduction in the strength of the returned signal for distributed targets, the noise generated by spurious reflections is greatly reduced compared with monostatic systems.

25

To obtain optimum performance from bistatic lidar systems, the transmitted and received beam foci must coincide with the location of beam intersection. This is because the transmit and receive optics must be separately focused and also adjusted in angle (i.e. "squinted") to ensure intersection of focused receive and transmit  
30 beams at the desired range. It should be noted that herein the term receive beam is used to denote the region from which any returned light will be directed to the

detector. In other words the receive beam is not a beam of photons, but a pseudo or virtual beam that defines the area from which light is received by the system.

5 A method of aligning a bistatic CLR prior to taking a measurement is described in WO01/35117. However, it can be seen that whenever the range of the equipment is altered it is necessary to recalibrate the system alignment using the alignment method. The requirement to perform a calibration step each time the system range is altered greatly reduces the flexibility and user-friendliness of the lidar system.

10 It is an object of the present invention to mitigate at least some of the disadvantages of bistatic lidar devices described above.

According to the present invention, a bistatic laser radar device comprises a transmit channel for forming a focused transmit beam, and a receive channel for forming a  
15 focused receive beam, wherein the device is arranged such that the focus of the transmit beam and the focus of the receive beam fall on a common axis when focused to a distance within the operable distance range of the device.

The present invention thus provides a bistatic lidar device in which squint is  
20 adjusted in a predetermined manner as the focus of the transmit and receive beams are varied. This allows, over the required distance range at which the device operates, the foci of the transmit and receive beams to intersect.

In other words, the location of the transmit beam focus position will trace a first axis  
25 over the operable distance of the device. The receive beam focus position will trace a second axis as its focus position is changed within the operable distance range of the device. The present invention ensure that the first axis and the second axis are substantially coincident within the operable range of the device; i.e. the foci of the transmit beam and the receive beam fall along a common axis. It should be noted  
30 that the common axis may, or may not, be linear depending on the exact geometry employed.

As described above, device performance is optimised when the foci of the transmit and receive beams intersect at the desired remote target. An advantage of the present invention over prior art bistatic lidar devices is thus the removal of the requirement to perform a separate squint adjustment step whenever the focus of the transmit and receive beams is altered.

Conveniently, the transmit channel comprises a first optical arrangement configured to form the focused transmit beam and having at least one lens. The first optical arrangement may be a single lens or may comprise a telescopic lens system.

Preferably, laser radiation is passed to the first optical arrangement via a transmit optical fibre cable. Hence, the focus of the transmit beam is adjustable by variation of the relative position of the first optical arrangement with respect to the exit aperture of the transmit optical fibre cable.

Advantageously, the fibre exit aperture is linearly translatable with respect to the first optical arrangement. For example, the fibre optic cable end (i.e. the exit aperture) could be mounted on a linear translation stage and moved with respect to a fixed first optical arrangement (e.g. a lens).

Conveniently, the receive channel comprises a second optical arrangement configured to form the focused receive beam and having at least one lens. The second optical arrangement is preferably configured to couple received radiation in to a receive optical fibre cable.

Preferably, the focus of the receive beam is adjustable by variation of the relative position of the second optical arrangement with respect to the entry aperture of the receive optical fibre

Advantageously, the fibre entry aperture is linearly translatable with respect to the second optical arrangement. For example, the fibre optic cable end (i.e. the entry

aperture) could be mounted on a linear translation stage and moved with respect to a fixed second optical arrangement (e.g. a lens).

Conveniently, in the case of a device having a receive channel in which a fibre end is linearly translatable to the second optical arrangement and a transmit channel in which the fibre end is linearly translatable to the first optical arrangement, the exit aperture of the transmit optical fibre is linearly translatable along the optical axis of the first optical arrangement, and the entry aperture of the receive optical fibre is linearly translatable along an axis arranged at a predetermined angle to the optical axis of the second optical arrangement.

The ability to implement the present invention using a pair of linear translation stages (i.e. one stage to provide transmit beam focus and a second stage to provide receive beam focus with squint correction) provides an advantage over typical prior art devices.

Advantageously, the predetermined angle is calculated from the inverse tangent of the ratio of the separation of the transmit channel and receive channel to the focal length of the optical arrangement. A detailed description of how the predetermined angle is calculated is described below with reference to figure 3.

Preferably, the device may further comprise at least one additional receive channel.

In certain circumstances, it is desirable to provide a lidar system having two or more receive channels. For example, in the case of vibrometry measurements made from a hard reflective or light scattering surface (e.g. a window or wall) the laser speckle pattern may produce reflections having an intensity that varies significantly with the angle of observation. A single receive channel could thus be located in a null region and only receive a small return signal. Providing additional receive channels mitigates this problem, as a return signal will be detected by each of the two or more spatially separated receive channels. The two or more returned signals can be

combined (e.g. averaged in some way) or the higher intensity signal could be used to provide the required information.

Advantageously, the at least one additional receive channel provides at least one  
5 additional receive beam and the focus of the at least one additional receive beam is arranged to intersect the focus of the transmit beam within the operable distance range of the device.

Preferably, the device configured to interact with a distributed (soft) target. For  
10 example, the target could be a volume of air and wind speed measurements could be extracted from the device.

Alternatively, the device may advantageously be configured to interact with a hard target. The device may be used, for example, in vibrometry. For example, vibrations  
15 of machinery could be monitored in order to identify the onset of failure.

Preferably, the transmit beam is formed from radiation having a wavelength in the region of  $1.55\mu\text{m}$ . The device may, of course, be operated using radiation of any wavelength (e.g. infrared, visible, UV etc).  
20

The invention will now be described, by way of example only, with reference to the following drawings in which;

figure 1 demonstrates the focus and squint properties of a bistatic lidar,  
25

figure 2 shows a technique for focusing and squinting an all fibre lidar,

figure 3 shows the geometry of a bistatic lidar, and

30 figure 4 illustrates a bistatic lidar according to the present invention.

Referring to figure 1a, the transmitter 2 and receiver 4 of a bistatic lidar device are shown. The transmitter is configured to transmit a laser beam 6 that is focused on a probe volume 8. Similarly, the receiver 4 is configured to be focused on the same probe volume 8; in other words the so-called receive beam 10 of the receiver is also  
5 focused on the probe volume 8. Furthermore, the receiver 4 is tilted away from the z-direction by an angle  $\theta$  so that the focus of the receive beam 10 intersects the focus of the laser beam 6 at the probe volume 8.

The system of figure 1a thus shows a properly aligned bistatic lidar. The foci of the  
10 beams from the transmitter and receiver are co-incident at the probe volume 8.

Figure 1b illustrates the effect of altering only the foci of the transmitter and receiver of the lidar system of figure 1a. It can be seen that although the range to the focus (R) of the transmitter and receiver is shortened, the return signal can only be derived  
15 from the region of intersection 12. This reduces the sensitivity of the system.

Referring to figure 1c, the effect of altering only the relative angle between the transmitter and receiver of the system of figure 1a is shown. It can be seen that the return signal will actually be derived from the region of intersection 14, which is at a  
20 shorter range than the point of focus of the transmitter and receiver. Again this reduces the sensitivity of the system.

Figure 1 illustrates why both the focus and the squint of a bistatic system must be carefully adjusted so as to define the required probe volume. WO01/35117 describes  
25 a technique that has been developed to enable accurate alignment of the transmit and receive beam at a desired probe volume. The method of WO01/35117 involves detaching a section of the receiver optics, and directing a laser beam down the receiver so that a "real" receive beam is formed that precisely matches the spatial light mode into which light must be scattered in order to be detected by the receiver.  
30 The receiver and transmitter can then be focused and squinted so that the "real" receive beam and transmit beam intersect and are focused on the desired probe volume.

Referring to figure 2, a typical prior art method for varying the focus and squint of a fibre based bistatic lidar apparatus is shown.

- 5 Figure 2a illustrates how a beam of laser light 20 emitted from a fibre end 22 can be focused to a point 24 by a lens 26. Figure 2b shows how axial movement (i.e. along the z-axis in figure 2) of the fibre toward the lens can increase the range at which the laser beam is focused. Figure 2c demonstrates how lateral movement of the fibre end with respect to the lens can also provide a lateral movement of the focal point.
- 10 Control of such lateral movement permits the required amount of squint to be introduced. The required lateral and axial translations can be provided by separate manual (e.g. micrometer) or automated (e.g. motorised translation stage) means.

- As described above, the requirement to separately adjust the focus and squint of the
- 15 system to ensure optimal overlap of the transmit beam and the receive beam on the target adds complexity to the system.

- Referring to figure 3, it is demonstrated how the present invention implemented for a fibre based lidar system permits the squint and focus adjustments to be combined
- 20 in a single linear translation that ensures precise squint compensation as the focus is adjusted.

- Consider a bistatic system in which a transmit lens 40 is laterally separated from a receive lens 42 by a distance  $S$ . The optical axes of the transmit and receive lenses
- 25 are both aligned along the z-axis. Each lens has a focal length  $F$ , and a remote target  $T$  is located at a range  $R$  from the lenses.

- A first fibre end 44 is located a distance  $F+Z$  from the transmit lens 40, and a second fibre end 46 is located a distance  $F+Z$  from the receive lens 42. To provide squint,
- 30 the second fibre end 46 is located a distance  $X$  away from the optical axis of the receive lens 42.

Hence, the focus condition of the system can be described using the expression;

$$\frac{1}{F+Z} + \frac{1}{R} = \frac{1}{F} \quad (1)$$

5 This expression can be re-written as;

$$Z = \frac{RF - RF + F^2}{R - F} = \frac{F^2}{R - F} \quad (2)$$

As an approximation, it can be seen that;

10

$$Z \approx \frac{F^2}{R} \quad (3)$$

For an axial movement of  $Z = 15\text{mm}$ , and assuming a focal length of  $15\text{cm}$ , the minimum range of the system is  $1.5\text{m}$ .

15

The required amount of squint as a function of range is given by the expression;

$$\frac{S}{R} = \frac{X}{F} \quad (4)$$

Hence, it can be seen that;

20

$$X = \frac{FS}{R} \quad (5)$$

For a range of  $1.5\text{m}$  (i.e. the minimum range of the system as derived from equation 3 above) a required lateral movement ( $X$ ) of  $8\text{mm}$  is required.

25

Therefore, the present invention lies in the realisation that both  $X$  and  $Z$  vary with the inverse of the range ( $R$ ). In other words, it has been found to be possible to achieve focus and squint with a single linear adjustment of the fibre end of the

receive optics. The angle ( $\theta$ ) at which a linear adjustment of the fibre end would result in both the desired focus and squint change can be calculated as;

$$\tan \theta = \frac{X}{Z} = \frac{F.S}{R} \cdot \frac{R}{F^2} \approx \frac{S}{F} \quad (6)$$

5

Thus, in the case of  $S = 8\text{cm}$  and  $F = 15\text{cm}$  an angle ( $\theta$ ) of approximately  $28^\circ$  would be required.

It should be noted that the angle ( $\theta$ ) calculated using equation (6) assumes that the range  $R$  is significantly greater than the focal length  $F$  of the lens. Equation (6) thus starts to break down when the range at which the beams are focused becomes comparable with the focal length.

For light of wavelength  $\lambda$  and having a radius  $r$  at the exit aperture, the lateral displacement ( $\Delta L$ ) error required to introduce a 3dB loss is given by;

15

$$\Delta L_{3\text{dB}} \approx \pm \frac{R^2}{\pi r^2} \lambda \quad (7)$$

Hence, the minimum range of operation of the system (i.e. the range where the loss is greater than 3dB) is given by;

20

$$R \approx r \sqrt{\frac{\pi \Delta L}{\lambda}} \quad (8)$$

25

A beam of radius  $1.8\text{cm}$  at the exit aperture having a wavelength of  $1.55\mu\text{m}$  would thus provide a squint error less than 3dB for all ranges greater than about ten metres.

It can thus be seen that alignment of the present invention remains close to optimum for longer range (i.e. beyond around  $20\text{m}$ ) applications such as vibrometry. However, some deterioration in sensitivity is encountered at short range (i.e. less

than around 10m) due to the increased importance of higher-order terms in the focus calculation.

5 The scheme would normally be implemented with zero squint on the transmit beam, and with the receive fibre mounted on a translation stage aligned diagonally to the optical axis of the receive lens. Alternatively, the T and R modes can be equally squinted in opposing directions by half the amount in the preceding version. In each of these methods, the number of translation stages is reduced from three (two focus and one squint) to two (one focus and one focus/squint, or two focus/squint).

10

The benefits of the present invention are increased when more than one receiver aperture is employed; for example in a dual-receiver or multiple receiver system.

15 Referring to figure 4, a fibre based lidar system according to the present invention is shown. The bistatic lidar system comprises a transmit channel 60 and a receive channel 62. The transmit channel 60 comprises a first fibre end 64 mounted on a first linear translation stage 66. A first lens 68 is provided to focus light exiting the first fibre end 64 to a remote target 70. The receive channel 62 comprises a second fibre end 72 mounted on a second linear translation stage 74. The axis of the second  
20 linear translation stage 74 is oriented at an angle  $\theta$  to the optic axis of a second lens 76 that is provided to collect light returned from the remote target.

Figure 4a illustrates the lidar system configured to interrogate a first target volume 78, whilst figure 4b illustrates the lidar system when configured to interrogate a  
25 second target volume 80. The angle  $\theta$  is selected using the criteria set forth with reference to figure 3 above such that the linear translation used to change the focus of the transmit and receive channels inherently causes a change in the squint of the system. This ensures that, for a given range of target distances, the transmit and receive beams are both focused and arranged to intersect at the required remote  
30 target.

As described above, the ability to make a single adjustment to each of the receive transmit channels to vary both the focus and squint of the system is quite advantageous. The present invention permits the range of the system to be varied whilst ensuring continued intersection of the transmit and receive beams. The  
5 requirement of prior art devices for the calibration of beam foci and intersection for each range at which the lidar is to be used thus becomes redundant.

In non-fibre based lidar systems a focus effect can be achieved by the movement of a lens along the optical axis of the transmitter and receiver telescopes. Translation of  
10 a lens away from the optical axis of the telescope can also be used to adjust the squint of the beam produced by that telescope. A skilled person would recognise that the present invention could also be applied to systems based on free space optics (i.e. non-fibre based). In other words, a linear translation of a telescope lens along a  
15 path at a given angle to the optical axis of the telescope could provide integral squint and focus correction in a similar manner to that described above for fibre based devices.
